It is widely accepted that information erasure entails heat dissipation. Here we analyze asymmetric memory states to show that this energy cost can be shuffled around to any step in a write-erase cycle and need not accompany the logically irreversible step in a computation. We discuss the resulting symmetry between logically irreversible and reversible operations, along with the implications for resolutions of Maxwell's demon paradox.

PACS numbers: 05.90.+m, 89.70.+c

Landauer argued that the act of destroying information during a logical operation carries with it an unavoidable dissipation of heat [1]. However, he only explicitly considered bits with a symmetric physical structure (Fig. 1a) and claimed that the basic physical results hold more generally. Consequently, it is commonly held that there exists the following fundamental physical distinction between logically irreversible operations and logically reversible ones: the former are always accompanied by an increase of entropy in the environment while the latter are dissipationless in principle.

In this letter, we prove that logically irreversible operations – that is, operations that erase information – can indeed be dissipationless in principle. We consider asymmetric bits (e.g. Fig. 1b) to show that information erasure exhibits an energy cost only in a complete computational cycle. All logically irreversible operations can be performed without increasing the entropy of the surrounding environment, provided that they change the average number of ONES and ZEROS in the bits on which they act.

The crucial observation is that while information erasure may entail a decrease in the Shannon entropy [2] of the system representing the information, additional asymmetries can be incorporated into the physical structure of the bits to contain this entropy change entirely within the system itself. These asymmetries will in turn necessitate heat dissipation during a logical operation that returns the bits involved in the computation to their initial statistics.

The traditional argument for Landauer's ideas is an intuitive one: the erasure of information takes a bit that could have been in two distinct states, ZERO and ONE, and sets it to a single predefined state regardless of its initial value. This decreases the number of possible physical states that the bit can occupy by roughly a half, implying a decrease in the entropy of the physical system representing the information by $k \ln 2$ per bit, where k is

FIG. 1: Potential energy diagrams for the information-bearing degree of freedom of a bit. Diagonal lines represent the possibility of finding a randomly chosen bit in various places in the bistable potential well. Before the reset operation, ZERO and ONE are occupied with equal probability.

Boltzmann's constant.

To be precise, let us represent a bit of information as the position of a particle in a one-dimensional bistable potential that is permanently coupled to a thermal bath at temperature T . If the particle is in the region $x < 0$, we will say that the bit is in the ZERO state, otherwise it is in the ONE state. A practical bit must be static, thus the potential barrier between the two minima must be much larger than kT and so we will assume that each bit is locally in thermal equilibrium but cannot cross the barrier on time-scales that are of interest to us. If we consider a set of bits where each bit is ZERO with probability p_0^s and ONE with probability p_1^s , then the probability that a particle in a randomly chosen bit is at position x is given by

$$\rho(x) = \begin{cases} p_0^s \rho_0(x) & \text{for } x \leq 0 \\ p_1^s \rho_1(x) & \text{for } x \geq 0 \end{cases} \quad (1)$$

$\rho_0(x) \simeq \frac{e^{-\beta U(x)}}{\int_{-\infty}^0 e^{-\beta U(x)} dx}$ and $\rho_1(x) \simeq \frac{e^{-\beta U(x)}}{\int_0^{\infty} e^{-\beta U(x)} dx}$ are each (approximately) normalized Boltzmann probability distributions for the two states, where $\beta \equiv \frac{1}{kT}$ [16]. It should be emphasized that the probability distribution

*Present Address: *Department of Physics, Massachusetts Institute of Technology, Cambridge, MA 02139*

of ONES and ZEROS is not determined by the thermodynamics of the system; it is externally imposed by the computation.

The Gibbs statistical entropy of such a set of bits is defined to be $S_G = -\int_{-\infty}^{\infty} \rho(x) \ln \rho(x) dx$. In the RESET-TO-ONE operation, the entropy change of the system for the case where the potential is symmetric about the origin and $p_0^s = p_1^s = 1/2$ is $\Delta S_G = -k \ln 2$.

Note that it is not the thermodynamic entropy that decreases by $k \ln 2$, but rather the Gibbs statistical entropy. To use this as a bound on the heat dissipated requires care – the second law is a statement about thermodynamic entropy and thus will not suffice. The literature in this regard has led to some controversy; some authors [3] have simply considered bits that are initially in a global thermal equilibrium between the two logical states, giving way to objections [4, 5] that any realistic bit must be static and thus cannot be in such an equilibrium. A recent argument by Chris Jarzynski [6] shows that the heat dissipated into the environment is in fact bounded from below by $-T\Delta S_G$. In this case, the heat dissipated into the environment is indeed at least $kT \ln 2$.

An important assumption of Landauer’s argument, and one that is implicit throughout nearly all of the literature on this subject [7] without any serious discussion, is that the physical realization of the bit is symmetric between the ZERO and ONE states [17]. However, bits are often represented in physical systems that do not necessarily have complete symmetry between the two logical states. Relaxing this assumption will show that the oft-made distinction between logical irreversibility and reversibility can be turned around: asymmetric bits allow for situations in which the energy cost of information erasure appears solely during the logically reversible step in a computation.

To prove this, we will consider a specific physical implementation of a general logically irreversible operation and explicitly analyze its energy cost. First consider the following toy example. Suppose that we have a bit of information that is represented in a physical system, again permanently coupled to a thermal bath at temperature T , where ZERO consists of a single physical state with energy $U_0 = 0$ and ONE consists of four distinct physical states, each with energy $U_1 = 2kT \ln 2$. Suppose further that there exists a large potential barrier between the ZERO and ONE states so that the bit is static over any time-scale of interest.

The following RESET-TO-ONE operation, performed on a set of bits with probability distribution $p_0^s = p_1^s = 1/2$, is dissipationless on average. Step 1: Instantly remove the barrier and allow the system to equilibrate with the bath. Step 2: Perform work to quasi-statically increase the energy of the ZERO state to an arbitrarily large final energy $U_f \gg kT$. Step 3: Leaving a large barrier like the original one, instantly reduce the energy of the ZERO state back to zero.

The barrier removal is instantaneous and requires no work; since the average change in the internal energy of the bits is also zero, the first law implies that step one is dissipationless on average. Step two is a thermodynamically reversible transformation and hence the heat dissipated is $Q_2 = -T\Delta S_2$, where ΔS_2 is the change in entropy in step two. Using the first law again for step three, $Q_3 = 0$ because the work performed on the system and the average change in internal energy are both zero. Therefore the total heat dissipated in this RESET-TO-ONE operation, averaged over the distribution of ZEROS and ONES, is $\langle Q \rangle_{total} = -T\Delta S_2 = 0$.

A similar calculation shows that ΔS_G is also zero. Observe, however, that to return to the initial state of 1/2 ONES and 1/2 ZEROS through a logically reversible operation such as NOT will be fundamentally dissipative.

Subsequent to Landauer’s distinction between logically irreversible and reversible operations, a number of researchers showed that all computations could be performed using solely reversible logic gates [8, 9]. The recurring theme throughout all of these implementations of reversible logic is the use of extra bits to store additional information about the inputs; a closer look at the preceding example reveals an analogous situation.

Suppose that the four states in the ONE configuration of the previous example are separated from each other by potential barriers and that the precise physical state of the bit after the RESET-TO-ONE operation depends on the input. In this case the operation is in some sense logically reversible, for a closer examination of the output will reveal the input. Just as with reversible logic gates, the asymmetry provides the extra scratch space to store the necessary additional information. Without the extra space, this additional information would leak out into the non-information-bearing degrees of freedom in the environment and result in heat dissipation.

In reality though, the barriers between the four states need not exist and thus the local thermalization of the ONE state implies that this information truly does get destroyed without any average change in entropy of the system or environment. The advantage of this outlook is in demonstrating the necessity of this additional scratch space and that its incorporation into the physical structure of the bit can keep the entropy changes isolated from the environment.

Now we will generalize the previous example. Suppose that each bit under consideration can be represented as the position of a particle in an asymmetric one-dimensional bistable potential, $U(x)$, with the ZERO and ONE states as defined earlier. We will set the zero of energy to be the average internal energy of the ZERO state and let U_1 denote the average internal energy of the ONE state; U_b will denote the height of the barrier and δ its width. As before, the system will be permanently coupled to a thermal bath at temperature T .

Let $f(\alpha_1, \alpha_2, \dots, \alpha_n)$ be any arbitrary n -input Boolean

function, with the inputs $\{\alpha_i\}$ chosen randomly from a set of bits with probability distribution $\{p_0^s, p_1^s\}$. The physical process carrying out this operation will act on $n + 1$ bits and will consist of their evolution under a time-dependent Hamiltonian $H(\{x_i(t)\}, t)$ that first sets the $(n + 1)^{th}$ bit to f and then the n input bits to ONE. Here $x_i(t)$ is the position of the particle in the i^{th} bit at time t . Let $\{p_0^f, p_1^f\}$ be the probability distribution of the bits once the operation is completed.

There are generally an infinite number of Hamiltonians that will serve as suitable physical implementations of the function f , but for simplicity we will consider those that add to the j^{th} bit a potential $V_j(\{x_i\}, t)$ with the following properties:

1. $V_{n+1} = 0$ for $t < 0$ and $t > \tau$.
2. At a short time δt after the operation begins, the effect of $V_{n+1}(\delta t)$ is to lower the potential barrier separating the two logical states of the bit to U'_b . This will be an instantaneous change in the limit $\delta t \rightarrow 0$.
3. As $t \rightarrow (\tau - \delta t)$, V_{n+1} slowly raises the potential of either the ZERO or ONE side depending on the n input bits. In the limit that $\tau \rightarrow \infty$, this is a thermodynamically reversible transformation.
4. In the remaining time, $V_{n+1} \rightarrow 0$, which is also an instantaneous change in the limit $\delta t \rightarrow 0$.
5. For all other j , the evolution of V_j is similar to that of V_{n+1} except that it begins at time $t = \tau$ and always raises the potential of the ZERO states once the barrier is lowered.

Note that this procedure is entirely memoryless: the Hamiltonian at time t does not depend on the earlier states of the bits and hence the information about the inputs truly is erased if f is a logically irreversible function. We will analyze this process in the limit $\tau \rightarrow \infty$ and $\delta t \rightarrow 0$, and observe that the evolution of the potentials can be divided into three steps. In the first step, the potential barrier separating the ZERO and ONE states is instantly lowered to U'_b . The second step consists of a thermodynamically reversible transformation that leaves the bit in the ONE state p_1^f of the time by raising the potential of the ZERO states, and in the ZERO state p_0^f of the time by raising the potential of the ONE states. The last step instantly drops the raised side of the potential back to its initial state, reverting back to the original potential before the operation began.

Let p_0^e and p_1^e denote the probabilities of being in ZERO and ONE, respectively, after the barrier is initially lowered and the bit allowed to reach thermal equilibrium with the bath. Furthermore, let $Z_0 = \int_{-\infty}^0 e^{-\beta U(x)} dx$ and $Z_1 = \int_0^{\infty} e^{-\beta U(x)} dx$ be the partition functions for the ZERO

and ONE states respectively. Finally, $\langle \dots \rangle$ will denote an average over the distribution of ONES and ZEROS.

Step one is an instantaneous change and requires arbitrarily little work if U_b is large enough and δ is small enough. Thus the heat dissipated during this step, $\langle Q \rangle_1$, is the average change in internal energy: $\langle Q \rangle_1 = -\langle \Delta U \rangle_1 = U_1(p_1^s - p_1^e)$. Step two is a thermodynamically reversible transformation, thus the second law implies that the heat dissipated is $\langle Q \rangle_2 = -T \Delta S_2$, where ΔS_2 is the change in entropy of step two. Using the first law again for step three, we find that $\langle Q \rangle_3 = 0$ because this is an instantaneous process where both the work performed on the system and the average change in internal energy are negligible. Using the well-known result in equilibrium statistical mechanics that $F \equiv -kT \ln Z = U - TS$, where $Z = \int e^{-\beta U(x)} dx$ is the usual partition function, we can write the average total dissipated heat during this operation as $\langle Q \rangle_{total} = -\langle \Delta U \rangle_1 + \langle \Delta F \rangle_2 - \langle \Delta U \rangle_3$, where

$$\langle \Delta F \rangle_2 = (-p_0^f kT \ln Z_0 - p_1^f kT \ln Z_1) + kT \ln(Z_0 + Z_1). \quad (2)$$

The total heat dissipated per bit is therefore

$$\langle Q \rangle_{total} = U_1(p_1^s - p_1^e) + kT \ln \frac{Z_0 + Z_1}{Z_0^{p_0^f} Z_1^{p_1^f}} - U_1(p_1^f - p_1^e), \quad (3)$$

and so for zero dissipation we require that

$$e^{\beta U_1(p_1^f - p_1^s)} = \frac{Z_0 + Z_1}{Z_0^{p_0^f} Z_1^{p_1^f}}. \quad (4)$$

Since $\frac{Z_1}{Z_0} = \frac{p_1^e}{p_0^e}$, we can rewrite the right hand side of eqn. (4) as $(\frac{p_1^e}{p_0^e})^{-p_1^f} (1 + \frac{p_1^e}{p_0^e})$. As a result we are led to study the properties of the following function:

$$f(\eta) = \frac{1 + \eta}{\eta^p} \text{ for } \eta \geq 0 \text{ and } 0 \leq p \leq 1. \quad (5)$$

A simple analysis shows that $\ln f(\eta)$ continuously takes on all values in the set $[-p \ln p - (1 - p) \ln(1 - p), \infty)$. Letting $\eta = \frac{p_1^e}{p_0^e}$ and $\gamma = e^{\beta(p_1^f - p_1^s)}$, eqn. (4) becomes $U_1 \ln \gamma = \ln f(\eta)$.

Now observe that given any $\gamma \neq 1$, we can set U_1 and p_1^e/p_0^e such that the above equation is satisfied. For the case where $\gamma = 1$, however, it cannot be satisfied except for the trivial situation in which $p_1^f = 0$ or 1 , which corresponds to both the input and output sets of bits being identically ONE or ZERO.

In the case of a RESET-TO-ONE operation, not only can the heat dissipated into the thermal bath be made arbitrarily small, but so too can the work necessary to carry out the procedure. The average work, $\langle W \rangle$, performed on each bit is simply the average change in

free energy during step two; for RESET-TO-ONE, this is $\langle W \rangle = kT \ln(1 + \frac{Z_0}{Z_1})$. By setting the width of the ONE well to be much greater than the width of the ZERO well, $\frac{Z_0}{Z_1}$ can be made arbitrarily small; eqn. (4) can simultaneously be satisfied if U_1 changes accordingly.

The preceding analysis indicates that there are other possibilities as well. For instance, an erasure process can absorb heat and cool the environment. Heat must be dissipated only in returning the bits involved in the computation to their initial statistics. However, it is still reasonable to follow Landauer in attributing this ultimate energy cost to information erasure. To see this, consider the following write-erase cycle. Suppose that we reset to ONE a sequence of bits with probability distribution $\{p_0, p_1\}$. If this probability distribution does not correspond to the equilibrium Boltzmann distribution of the bits, $\{\frac{Z_0}{Z_0+Z_1}, \frac{Z_1}{Z_0+Z_1}\}$, then first we adjust the energy difference between the two states until the thermal equilibrium distribution does correspond to the statistical distribution of the bits. This would not dissipate heat, but would require some amount of work. Then, using the algorithm prescribed earlier, – lowering the barrier, raising one side and reinserting the barrier – the average heat dissipated can be calculated to be

$$\langle Q_{erase} \rangle = -p_0 T(S_1 - S_0) - kT(p_0 \ln p_0 + p_1 \ln p_1), \quad (6)$$

where S_0 and S_1 are the entropies of the ZERO and ONE states, respectively. After the erasure, we readjust the energy difference between the two states to its initial position, again without any additional heat dissipation.

To now restore the original sequence of bits, we wish to perform a logically reversible write procedure. In this case the average heat dissipation is $\langle Q_{write} \rangle = -T p_0(S_0 - S_1)$, and so the net heat dissipation in the write-erase cycle is

$$\langle Q_{total} \rangle = -kT(p_0 \ln p_0 + p_1 \ln p_1), \quad (7)$$

which is directly related to the information theoretic entropy change in the erasure step. Thus, while the erasure step itself can be performed without any net heat dissipation or work input, the energy cost that appears in a complete write-erase cycle is a direct result of the information loss.

It is difficult to overstate the impact that Landauer's argument has had on our present understanding of the fundamental limits of computation and the various paradoxes involving the second law of thermodynamics. Charles Bennett's famous resolution of the Maxwell demon paradox [10, 11] points to information erasure as the single phenomenon that ultimately saves the second law; the reason Szilard's engine [12] cannot turn heat into work, it has been argued [13], is because information must be erased in completing a cycle of operation,

necessarily dissipating exactly enough heat to save the second law. Earman and Norton's counterexample [14] to the thesis of reversible measurement is flawed, as Bennett [15] points out, because it performs a logically irreversible change in the flow of control of data, hence dissipating heat.

In contrast, the arguments made above illustrate that our current understanding of information erasure requires modification. Landauer correctly attributed an energy cost to erasure, but this cost can be shuffled around to any step in a sequence of operations that returns the final distribution of ONES and ZEROS to the original one, regardless of logical reversibility. In discussions of Maxwell's demon or Szilard's engine, it is therefore impossible to point to a single step as being the fundamentally dissipative one without knowledge of the specific physical system instantiating the bits.

It is a pleasure to thank Jay Deep Sau and Gavin Crooks for many enjoyable and insightful conversations. I would also like to extend my profound gratitude towards Chris Jarzynski, Wojciech Zurek, Umesh Vazirani, Joel Moore, John Clarke, Peter Shepard, and Ari Siletz for helpful discussions and commenting on various drafts of the paper.
